## Abstract

We examined the extent to which lay people and health professionals are able to assess occurrence risks for multifactorial diseases. We asked 341 participants to assess the risk of developing lung cancer, coronary artery disease or rheumatoid arthritis in 16 scenarios, each featuring a combination of four factors (family history, daily alcohol intake, daily tobacco consumption and genetic test results). Participants considered all factors. However, they accorded more weight to tobacco and genetic test results. Moreover, it appears that where one of the factors (e.g. the presence of the incriminated gene) exerted a strong influence, the influence of the other factor(s) was correspondingly weaker. The health risk judgements of health professionals were more dependent on the specific disease and were also influenced to a greater degree by genetic information than lay people.

## Keywords

coronary artery disease, genetic susceptibility, health behaviour, health risk assessment, lung cancer, rheumatoid arthritis

## Introduction

As more and more risk factors emerge as probable causes in disease aetiology, the question of how they interact, be it through synergy (positive interdependence) or through antagonism (negative interdependence), is increasingly important (Rothman, 1976). For most common diseases, there are nearly always some genetic and environmental component causes. In other words, virtually every case of every disease has some environmental and genetic component causes and can thus be attributed both to genes and to the environment (Rothman, 1976; Rothman and Greenland, 2005). For example,

rheumatoid arthritis (RA) develops mainly because of certain genes (Chibnik et al., 2011), but tobacco consumption can also influence the risk of the disease developing in at-risk patients

(Bang et al., 2010; Källberg et al., 2011; Lahiri et al., 2012). Similarly, the major risk factor for the development of lung cancer is cigarette smoking, but multiple genetic factors may also play a role (Marshall and Christiani, 2013; Molina et al., 2008; Myneni et al., 2013; Wang et al., 2013), while coronary artery disease is the result of harmful interactions between genetic and environmental factors such as smoking, poor diet, lack of exercise and alcohol consumption (Gränsbo et al., 2013; Kulbertus and Lancellotti, 2012; Pun et al., 2013; Sobenin et al., 2013).

Clinical epidemiology is about examining risk factors in conjunction with each other in order to arrive at a correct assessment of overall health risks. However, the way in which people draw all this information together can run counter to good epidemiological practice. An example of the discrepancy between the objective epidemiological model and people's mental models is provided by Hermand et al. (1997), who asked 64 participants to estimate the level of cancer risk in a number of situations where tobacco consumption was associated with that of alcohol. Although the participants were generally aware that the consumption of tobacco and alcohol can have a serious impact on the level of cancer risk, instead of representing the combined effects of tobacco and alcohol consumption in a summative or synergistic way, they apparently considered that indulging highly in just one of these two dangerous behaviours is enough to result in a maximum risk of cancer: A heavy smoker was thought of as not having much to lose if he or she was also a heavy drinker. Similarly, a heavy drinker was also thought of as not having much to lose if he or she was a heavy smoker. Their perception of how the effects of the two substances interact corresponded to Rothman's (1976) antagonism model. It was, however, in complete contradiction with their answers to a questionnaire, which revealed their knowledge to be almost scientific (see, for example, Kozlowski and Ferrence, 1990; Rosengren et al., 1988; Saracci, 1987). Another example is the discrepancy between people's awareness of cardiovascular

disease and their failure to perceive themselves as being at risk: In women attending a cardiovascular health-screening event, 99 per cent were aware that cardiovascular disease is the leading cause of death among women. However, only approximately half (47%) perceived themselves to be at personal risk, even though 65 per cent were determined to be 'at risk' and 12 per cent at 'high risk' according to guidelines. Of the 228 participants, 'at risk' or 'high risk' 48 and 21 per cent, respectively, did not perceive themselves to be at risk at all (Kling et al., 2013).

Other studies have reported similar misconceptions regarding the combined effect of health risks, with cases of risk underestimation associated with weight (Vandelanotte et al., 2011), cancer (Mattson et al., 1987; University of California at Berkeley, 2007), cancer and heart disease (Ayanian and Cleary, 1999) and hookah smoking (Noonan and Patrick, 2013).

Nevertheless, people can be taught to draw together information relating to diverse health risks, and simple techniques have proved successful in teaching lay people how to employ the synergetic combination model. For example, Bonnin-Scaon et al., (2002) examined the effect of outcome feedback on training to develop the ability to assess the multiplicative relationship between daily intakes of tobacco and alcohol, and the risk of oesophageal cancer. In the first of two experiments, 65 French adults assessed the risk of oesophageal cancer associated with a combination of five different levels of tobacco and five of wine. They assessed them both before and after training sessions in which they were shown the actual risk for each vignette. In the second experiment, 35 French adults underwent the same evaluation and training and were reassessed a month later. Results indicated that prior to the training sessions, the participants used a subadditive rule to combine the perceived risks of oesophageal cancer due to smoking and drinking. After just one training session, they changed to the multiplicative rule consistent with epidemiological data. However, only a limited range of risk factors were examined in this study, and none of them were genetic. Of the

few studies of genetic factors that have been conducted among the general population, one has indicated that when genes and behaviour are presented as being damaging to health, the majority of the population adopts an additive model (with approximately one-third adopting an amplifying model). In the gain frame (genes and behaviour presented as being health-protecting), assessments are divided roughly equally between additive, amplifying and sub-additive models (Condit and Shen, 2011). Other studies have highlighted misconceptions about the results of the direct-to-consumer genetic tests (Leighton et al., 2012), and misconceptions also appear when the genetic and environmental causes of breast and colorectal cancer are studied (Wang et al., 2010). In the case of cardiovascular disease, people produce fatalistic responses and believe that little can be done to reduce the risk when genetic risk information (vs family history and/or cholesterol testing) is provided (Claassen et al., 2010).

Other research has studied the perceptions of focus groups (e.g. at-risk groups in the population, patients or patients' relatives). The impact of genetics varies according to the study and the disease under scrutiny. All participants with relatives who are alcoholics, for instance, attribute the alcoholism in their families to multiple factors – often a combination of biological, genetic and environmental ones – as well as to personal characteristics (Gamm et al., 2004). Among those at risk of cardiovascular disease, findings suggest that family history may be more important than DNA information when it comes to explaining perceptions of and responses to risk (Claassen et al., 2012). Among the overweight participants with a high phenotypic risk of Type-2 diabetes, an exploration of perceptions of genetic risk testing for diabetes, compared with currently available prediction methods based on non-genetic risk factors (e.g. family history, abnormal fasting blood glucose levels and obesity), revealed that many participants 'conferred a unique value' on information about their genetic risk, that is, they considered only the genetic risk in the risk to develop the disease (Markowitz et al., 2011). Similarly, a study examining risk perceptions

among patients with an increased risk of cancer showed that prior to genetic counselling, all the participants estimated their risk as being higher than it actually was (Rantala et al., 2009). Furthermore, in a review of the impact of genetic counselling on risk perception, results suggested that 'genetic counseling may have a positive impact on the accuracy of risk perception' (Smerecnik et al., 2009).

### *This study*

This study examined whether lay people are able to adjust their weighting of risk factors when judging the overall risk of developing a given illness. In other words, we examined the extent to which lay people are able to use the information available to them in a flexible way, attributing more weight to one risk factor (e.g. tobacco consumption) in one situation (e.g. judging the risk of developing lung cancer) and less weight to this same factor in another situation (e.g. judging the risk of contracting arthritis). This study also compared lay people's flexibility in weighting up risk factors with that of health professionals.

We should emphasize that the question examined in this study was not whether lay people mentally combine information in a correct and optimum way. Posing such a question would be largely meaningless because the answer is obviously no. We already know that people do not combine health risk information in an optimum way, because if they were able to do so, there would have been no need to develop the branch of medical science known as epidemiology. The very existence of epidemiology is direct proof of people's inability to combine risk information in an optimum way. Rather, this study was about the way people actually use and combine information. We simply wanted to know whether they are sensitive to risk factors (e.g. family history), whether they use them in a reasonable way (e.g. in the right direction), and whether they bear in mind the diversity of everyday life situations when using and combining information that corresponds to these risk factors.

This study, like many previous ones (e.g. Guedj et al., 2005; Igier et al., 2014), featured a set of scenarios, that is, participants were instructed to consider actual cases, indicating for each one the extent to which a given health risk was repeated. Three very different illnesses were considered: (a) lung cancer, known to be strongly associated with people's behaviour and environmental conditions; (b) RA, known to depend mainly on genetic factors and (c) coronary artery disease, known to depend on both sets of factors. The risk factors involved in the scenarios were those most commonly encountered in the literature on health risk assessments: (a) daily alcohol intake (no drinking habit vs heavy drinking habit), (b) daily tobacco consumption (non-smoker vs heavy cigarette smoker), (c) a history of illness in the family (uncle vs father) and (d) the results of a genetic test (presence vs absence of a specific gene). In summary, two of the risk factors were behavioural (alcohol intake and tobacco consumption) and two were genetic (family history and genetic test). We will assess the weight of the genetic factor in our study by using genetic test, although they are not currently used in medical practice.

### Hypotheses

Our first hypothesis was that all four risk factors would be used by the participants to judge the overall risk of contracting each illness. They would judge the overall risk to be higher in the presence of each of the risk factors (heavy drinking, heavy smoking, a genetically close family relative with the illness or the detection of the incriminated gene) than in the opposite case.

Our second hypothesis was that some of the risk factors at least would be used in an interactive way. This hypothesis was based on the findings from earlier studies showing that when lay people judge the risk of cancer on the basis of daily alcohol intake and tobacco consumption, they mentally combine the two factors in a disjunctive way, that is, when the weight of a factor prevails over the other (see also, Bonnin-Scaon et al., 2002; Hermand et al., 1997). We, therefore,

expected to observe an Alcohol  $\times$  Tobacco interaction and envisaged the possibility of a Tobacco  $\times$  Gene interaction, too.

Our third hypothesis was the central hypothesis in this study. We expected to observe several interactions between the four factors and the three types of illness. More specifically, we expected (a) more weight to be attributed to the two behavioural risk factors (alcohol and tobacco) for lung cancer than for RA and (b) more weight to be attributed to the two genetic risk factors (family history and genetic test) for RA than for lung cancer. We also expected the results for coronary artery disease to be midway between the ones observed for the other two illnesses. We, therefore, expected to see several Risk factor  $\times$  Type of illness interactions.

Our fourth hypothesis was that the health professionals would display greater flexibility in the weighting of the risk factors than the lay people. Accordingly, we expected to see several Participant group  $\times$  Risk factor  $\times$  Type of illness interactions.

## Method

### Participants

The lay people were approached and recruited by two trained research assistants in the city centre of Toulouse and the region of Midi-Pyrenees in south of France. Some 500 people were contacted altogether, and after receiving a full description of the procedure, 54 per cent of them agreed to take part. The professionals were contacted in workplace, in the clinics and hospitals of Midi-Pyrenees. All 341 participants (197 women, 144 men) were unpaid volunteers. They were informed about the goals of the study and asked to provide their written informed consent. Their mean age was 41.3 years (standard deviation (*SD*) = 13.52 years, range = 13–86 years). They included 271 lay people, 64 nurses and 6 physicians.

Of the 271 lay people, 50.44 per cent had a university degree and 49.56 per cent had completed secondary education but did not have a university degree.

## Material

The material consisted of 16 cards for each disease, each bearing a brief description of a scenario, followed by a question, and a response scale. The scenarios were constructed according to a four within-participant factor design, and the information was presented in the following order: (a) daily alcohol intake (practically no intake vs heavy drinking), (b) daily tobacco consumption (non-smoker vs heavy cigarette smoker), (c) history of illness in the family (uncle vs father) and (d) the results of a genetic test (presence vs absence of the incriminated gene). Sex and age were held constant: all the patients were aged about 45 years and identified as 'Mr'.

The question was 'In your opinion, what is the risk of Mr X developing [name of illness]?'. Participants had to rate their responses on a 15-point scale ranging from 1 (*No risk at all*) to 15 (*Very high risk*). Two examples are provided in Appendix 1. The cards were presented in a different random order for each participant.

## Procedure

The experiment took place in a single session, held in a vacant room in the hospital, the university or in the participant's home. Each person was tested individually. As recommended by Anderson (1982), the session came in two phases. In the first, familiarization phase, the participants were told by the person conducting the interview what was expected of them and presented with eight scenarios taken from the complete set of 16. They then provided a risk rating for each case. After completing the eight ratings, the participants were given the opportunity to review their responses and modify them.

In the experimental phase, all 16 scenarios were presented three times: once in the lung cancer condition, once in the coronary artery disease condition and once in the RA condition. The conditions were presented in a different random order for each participant. The participants were allowed to provide their ratings at their own pace but were no longer allowed to

review their responses or go back and change them as they had done in the familiarization phase. In both phases, the experimenters routinely checked that each participant, regardless of age or educational level, was able to grasp all the necessary information before producing a rating.

It took the participants 20–40 minutes to complete the familiarization phase and all three sets of scenarios. The experimental phase went quickly because the participants were already familiar with both the task and the material. They knew in advance how long the experiment would take. None of them complained about the number of scenarios they were required to judge. None of them complained about the believability of the scenarios. The research was approved by the university ethics committee, and a written informed consent was obtained from all the participants in the study.

## Results

An analysis of variance (ANOVA) was performed on the whole dataset. The design was Participant Group (lay people vs health professionals)  $\times$  Alcohol intake (no daily intake vs heavy drinker)  $\times$  Tobacco consumption (non-smoker vs heavy smoker)  $\times$  Degree of genetic proximity (uncle vs father)  $\times$  Presence of incriminated gene (yes vs no)  $\times$  Type of illness (lung cancer vs coronary artery disease vs RA). The main results are shown in Table 1. As we were running multiple comparisons, the significance threshold was set at .001.

Overall risk was judged by participants to be significantly higher: (a) for heavy alcohol intake ( $M = 9.13$ ,  $SD = 1.73$ ) than for abstinence ( $M = 7.59$ ,  $SD = 1.67$ ), (b) for heavy cigarette smoking ( $M = 9.97$ ,  $SD = 1.75$ ) than for abstinence ( $M = 6.74$ ,  $SD = 1.65$ ), (c) when the relative was the father ( $M = 8.75$ ,  $SD = 1.61$ ) rather than an uncle ( $M = 7.96$ ,  $SD = 1.66$ ), (d) when a specific gene was present ( $M = 10.04$ ,  $SD = 1.96$ ) than when it was absent ( $M = 7.67$ ,  $SD = 1.73$ ) and (e) when the illness was coronary artery disease ( $M = 9.03$ ,  $SD = 1.70$ ) rather than lung cancer ( $M = 8.74$ ,  $SD = 1.71$ ) or RA ( $M = 7.30$ ,

ANOVA: analysis of variance.

The higher order interactions that were not significant are not reported here.

$SD = 1.89$ ). A post hoc analysis using Tukey's honestly significant difference (HSD) test showed that only the difference between RA and the other two illnesses was significant.

Several two-way or three-way interactions involving risk factors were significant. The influence of tobacco consumption on risk judgements was weaker in the case of heavy alcohol intake (difference of 2.93 points between the highest and lowest levels) than in the case of abstinence (difference of 3.54). Similarly, the presence of the incriminated gene had a weaker effect on risk judgements in the case of heavy alcohol intake (difference of 3.13) than in the case of abstinence (a difference of 3.62). The presence of the incriminated gene had a weaker influence on risk judgements in the case of heavy tobacco consumption (difference of 3.00) than in the case of abstinence (difference of 3.75). In addition, the Alcohol intake  $\times$  Tobacco consumption interaction was weaker when the incriminated gene was present than when it was absent.

Several two-way or three-way interactions involving the type of illness were also significant. The effect of alcohol intake on risk judgements was stronger for coronary artery disease (difference of 2.23) than for the other two illnesses (difference of 1.24). Tobacco consumption had a stronger influence on risk judgements for lung cancer (difference of 4.75) than for coronary artery disease (difference of 3.57), and a stronger influence for coronary artery disease than for RA (difference of 1.39). The presence of the incriminated gene had a stronger influence on risk judgements for RA (difference of 4.25) than for the other two illnesses (difference of 2.95). In addition, (a) the Alcohol intake  $\times$  Tobacco consumption interaction was stronger for coronary artery disease than for the other two illnesses and (b) the Tobacco consumption  $\times$  Presence of gene interaction was weaker for RA than for the other two illnesses.

Several two-way interactions involving the participant group factor were significant. The alcohol intake effect was stronger among lay people (difference of 1.92) than among health

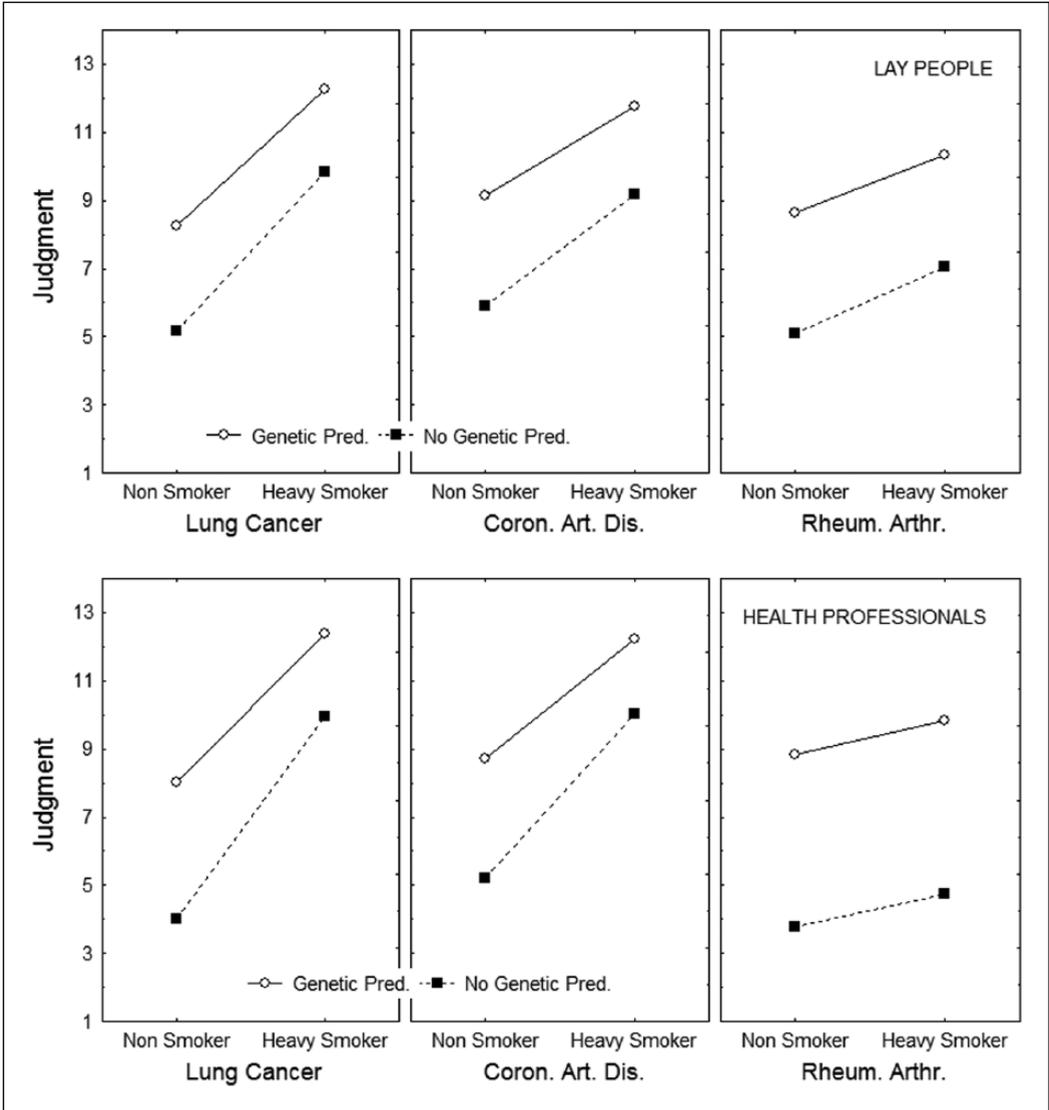

professionals (difference of 1.21). By contrast, the presence of the incriminated gene had a stronger effect among health professionals (difference of 3.72) than among lay people (difference of 3.03). Furthermore, the risk level associated with RA was lower among health professionals ( $M = 6.80$ ,  $SD = 1.87$ ) than among lay people ( $M = 7.79$ ,  $SD = 1.91$ ), although there was no difference regarding either of the other two illnesses.

Several three-way and four-way interactions involving both the type of illness and the participant group factor were significant. For example, the effect of tobacco consumption varied more as a function of illness type among health professionals than among lay people. Regarding RA, it was weaker among health professionals than among lay people, whereas in the case of lung cancer and coronary artery disease, it was stronger among health professionals than among lay people. Symmetrically, the effect of the presence of the incriminated gene varied more as a function of illness type among health professionals than among lay people. Regarding RA, it was stronger among health professionals than among lay people, whereas in the case of the other two illnesses there was no difference in strength. In addition, the Tobacco consumption  $\times$  Presence of incriminated gene  $\times$  Type of illness interaction was stronger among health professionals than among lay people (see Figure 1).

## Discussion

This study examined the flexibility of lay people and health professionals when it comes to weighting behavioural and genetic risk factors in order to judge health risks in different conditions.

Our first hypothesis, confirmed by the data, was that all the risk factors would be employed by the participants. As expected, overall risk was judged to be higher in the case of heavy (vs low) daily intake of alcohol, in the case of daily (vs zero) tobacco consumption, when a family relative with the illness was genetically close (vs distant) and when the incriminated gene was

**Figure 1.** Pattern of results observed for lay people (top panels) and health professionals (bottom panels). In each panel, the y-axis corresponds to the risk judgements, the x-axis bears the two levels of tobacco behaviour, two curves correspond to the two levels of genetic predisposition and the three panels correspond to the three diseases.

present (vs absent). This result demonstrates that the participants understood the task and responded appropriately to the scenarios. There were, however, striking differences in the impact of the different factors on participants' risk judgements. Thus, the presence of the incriminated gene and daily tobacco consumption

impacted on risk judgements far more than alcohol intake and family history did, explaining 46 and 42 per cent of the variance compared with 13 per cent for each the two remaining factors.

Our second hypothesis, again confirmed by the data, was that the risk factors would be used in an interactive way. In addition to the

Alcohol  $\times$  Tobacco interaction reported in earlier studies, we observed Alcohol  $\times$  Gene, Tobacco  $\times$  Gene and Alcohol  $\times$  Tobacco  $\times$  Gene interactions. Where one of the factors (e.g. the presence of the incriminated gene) exerted a strong influence, the influence of the other factor(s) was correspondingly weaker. In other words, participants mentally combined the information in accordance with Rothman's (1976) antagonism model, and with the findings reported by Hermand et al., (1997). This way of thinking showed that people did not make much difference in the risk assessment when they add a second bad behaviour.

Our third hypothesis, which was broadly supported by the data, was that participants would be flexible in the way they employed the information in the three illness conditions. The flexibility demonstrated by people is in accord with epidemiological evidence, that is, they changed their weightings correctly. We expected the two behavioural risk factors (alcohol and tobacco) to have a greater impact for lung cancer than for RA, and the two genetic risk factors (family history and genetic test) to have a greater impact for RA than for lung cancer. When judging the risk of contracting lung cancer, participants did indeed rely mainly on daily tobacco consumption, just as they relied mainly on the genetic test results to judge the risk of RA. Finally, they relied more on alcohol intake in the coronary artery disease condition than they did in the other two conditions. The only risk factor that did not interact with type of illness was family history, but as we have already indicated, this factor had only a weak impact.

Our fourth hypothesis, fully supported by the data, was that the health professionals would be even more flexible than the lay people in weighting the risk factors. In the three cases mentioned in the previous paragraph, the Risk factor  $\times$  Type of illness interaction was consistently stronger among the health professionals than among the lay people. In other words, the health professionals more gave weight to behavioural risk factors when judging the risk of contracting a behaviour-related illness, and additional weight to genetic-type factors when

judging the risk of contracting a gene-related illness than the lay participants.

Two further series of findings deserve comment. The first one concerns the Group participant  $\times$  Risk factor interactions: we found that genetic information had more impact in judging health risks among the health professionals than among the lay participants. This finding can be explained by the fact that health professionals are more frequently taught about the impact of genetics on the development of diseases than lay people are.

The second one concerns differences between the two groups in the strength of the Risk factor  $\times$  Risk factor interactions: As can be observed in Figure 1, these interactions were stronger among the health professionals than among the lay participants. In other words, the former combined the health risk information in a more antagonistic way (Rothman, 1976) than the latter did. On the face of it, this is a paradoxical finding, as it suggests that health professionals are even further from the optimum model than lay people. More research is needed to resolve this paradox, but if it is confirmed, this way of thinking might affect their decision making and advice to their patients and would need to be rectified. As shown by Bonnin-Scaon et al., (2002), outcome feedback can help people to combine risk factors correctly.

Our study has several limitations. First, the participants were limited to the people of Toulouse, France. Generalizations to other countries must, therefore, be made with care. Second, the sample of physicians was very small in size. The study findings will, therefore, need to be confirmed on other samples. Third, although the influence of the genetics was shown beyond doubt in the occurrence of the present diseases, these are not at present detected by the practice of genetic tests in general medicine. At least, the ratings were made about hypothetical scenarios, rather than real cases.

### *Implications*

Our results highlight the way in which people combine information about environmental and

genetic risk factors when judging the risk of developing lung cancer, coronary artery disease or RA. The implications are multiple. First, campaigns of prevention could be built from the way of thinking of the participants, notably to highlight the impact on health of interactions of multiple risks factors like tobacco, alcohol and genetics. Furthermore, as well as helping geneticists to adapt their explanations during their consultations, these results indicate that health professionals who are not specializing in genetics could be helped in their practice with a genetic in-house training.

### Declaration of conflicting interests

The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

### Funding

The author(s) received no financial support for the research, authorship, and/or publication of this article.

## Appendix I

### *Two examples of scenarios*

Mr Gibet is 42 years old. In his family, his father suffers from coronary artery disease. Mr Gibet only drinks alcohol on special occasions. He does, however, smoke more than a pack a day. Given his family history, his general practitioner arranges for him to undergo a genetic susceptibility test. The results indicate that Mr Gibet has the particular form of the gene potentially involved in this disease.

In your opinion, what is the risk of Mr Gibet developing coronary artery disease?

(15-point scale ranging from *no risk at all* to *very high risk*).

Mr Ribod is 45 years old. In his family, his father suffers from lung cancer. Mr Ribod regularly consumes large amounts of alcohol (the equivalent of more than a litre of wine per day). In addition, he smokes more than a pack a day. Given his family history, his general practitioner recommends a genetic susceptibility test. The results indicate that Mr Ribod does not have the particular form of the gene potentially involved in this disease.

In your opinion, what is the risk of Mr Ribod developing lung cancer?

(15-point scale ranging from *no risk at all* to *very high risk*)
